Title:

Virtual Histology Analysis of Carotid Atherosclerotic Plaque:
Plaque Composition at the Minimum Lumen Site and of the Entire Carotid Plaque.

Running Title: Virtual Histology analysis of carotid atherosclerotic plaque

Key words: carotid stenosis; plaque imaging; IVUS; Virtual Histology

This is the pre-peer reviewed version of the following article: [Tsurumi A, Tsurumi Y, Hososhima O, Matsubara N, Izumi T, Miyachi S. Virtual Histology Analysis of Carotid Atherosclerotic Plaque: Plaque Composition at the Minimum Lumen Site and of the Entire Carotid Plaque. J Neuroimaging. in press.], which has been published in final form at [Link to final article].
Abstract

Background and Purpose. Virtual Histology intravascular ultrasound, which is based on spectral and amplitude analyses of the intravascular ultrasound radiofrequency backscatter signals, allows reliable identification of four atherosclerotic plaque types: fibrous, fibrofatty, dense calcium, and necrotic core. To detect the relationship between the volumetric analysis of the entire plaque responsible for carotid artery stenosis and cross-sectional plaque analysis at the minimum lumen site, a retrospective, cross-sectional study of patients who underwent interventional therapy of atherosclerotic cervical carotid artery stenosis was conducted.

Methods. Forty-eight stenotic lesions in 45 consecutive patients were included in the study. Virtual Histology was obtained before predilatation for the carotid artery stenting procedure.

Results. Simple regression analysis revealed that the volumetric proportion of each plaque type correlated significantly with the corresponding plaque type area at the minimum lumen site. The adjusted coefficients of determination of the simple regression analyses were 0.782 (P < 0.001) for fibrous tissue, 0.741 (P < 0.001) for fibrofatty tissue, 0.864 (P < 0.001) for dense calcium, and 0.918 (P < 0.001) for necrotic core.

Conclusions. The plaque composition at the minimum lumen site represents the volumetric composition of the entire carotid plaque that causes atherosclerotic cervical carotid artery stenosis.

Introduction

For the treatment of patients with carotid artery stenosis, plaque imaging to analyze plaque characteristics is important to detect vulnerable plaque and avoid ischemic complications. Magnetic resonance imaging, computed tomography, positron emission tomography, carotid ultrasonography, and intravascular ultrasound (IVUS) have been reported as carotid plaque imaging devices. Several studies of coronary and carotid artery plaque imaging have demonstrated that Virtual Histology (VH; Volcano Corporation, Rancho Cordova, CA), which is based on spectral and amplitude analyses of the intravascular ultrasound radiofrequency backscatter signals, allows reliable identification of four atherosclerotic plaque types: fibrous, fibrofatty, dense calcium, and necrotic core. In addition, the geometric and compositional output of VH IVUS has been reported to be reproducible. Therefore, VH IVUS has been used to evaluate plaque characteristics in both coronary interventions and neurointerventions.

The authors have previously reported that periprocedural hypotension in carotid artery stenting can be predicted by volumetric VH IVUS analysis of the plaque responsible for the carotid artery stenosis. Volumetric analysis of the plaque, which can be achieved by performing integral analysis of the cross-sectional plaque analyses, is a time-consuming task. On the other hand, analyzing only one cross-section at the minimum lumen site is easier and faster than volumetric analysis.

The present study was conducted to identify the relationship between the volumetric analysis of the entire carotid plaque and cross-sectional plaque analysis at the minimum lumen site.
Methods

Study Design

A retrospective, cross-sectional study of patients who underwent interventional therapy to cervical carotid artery stenosis in a tertiary referral hospital from April 1, 2006 to April 30, 2007 was conducted. The VH IVUS data and demographic characteristics of each patient were gathered and recorded for the purpose of analyzing the relationship between the clinical prognosis in carotid artery stenting (CAS) and carotid plaque characteristics, which had been reported in our previous paper. All consecutive patients who underwent interventional therapy for cervical carotid artery stenosis in our hospital were registered and recorded in the present study. Patients with stenosis related to radiation therapy or with restenoses after carotid endarterectomy (CEA) were excluded from the present study. All patients underwent VH IVUS and volumetric and cross-sectional analyses of the carotid plaque. The patients who had stenosis that was too severe for the VH IVUS catheter to cross before predilatation for CAS were also excluded from the study.

Virtual Histology Acquisition

All procedures were performed under local anesthesia. A VH IVUS was obtained before predilatation for the CAS procedure. A VH IVUS catheter (Eagle Eye Gold, 3.5 F/20 MHz; Volcano Corporation) was placed distal to the stenotic lesion and manually pulled back proximal to the stenosis. During this pullback, color flow IVUS was recorded on the VH IVUS console. Then, the VH IVUS catheter was again advanced distal to the stenosis, and it was subsequently pulled back proximal to the stenosis by a motorized pullback system set at 0.5 mm/sec. During this pullback, raw radiofrequency data were captured on the VH IVUS console at the top of the R-wave of the electrocardiogram and recorded on a digital video disc. Each distance between the captured images was also recorded.

Analysis of Virtual Histology

The color-coded map superimposed on the gray-scale IVUS tomographic image was reconstructed from the captured raw RF data using the VH IVUS software (version 1.3; Volcano Corporation). Using the VH IVUS software, atherosclerotic plaques were characterized by classification trees based on mathematical autoregressive spectral analysis of IVUS backscattered data. The distal/proximal end frames were defined as the frames where the plaque within the media line was concentric and the diameter of the lumen within the intima did not change compared with more distal/proximal frames. Between the distal and proximal end frames, a media line and an intima line were manually drawn in each frame by referring to the adjacent frames and by referring to the corresponding color flow IVUS image, respectively. Referring to adjacent frames is useful in detecting the media line. The intima line can be detected easily using the color flow IVUS images showing the blood flow in the vessel. Since the VH IVUS software could not analyze the plaque within ulceration, the ulcerated area was considered to be within the intima line in VH IVUS analyses.

The total volume of each plaque type (fibrous, fibrofatty, dense calcium, and necrotic core) was calculated using the VH IVUS software and expressed in cubic millimeters. The volumetric proportion of each plaque type was also determined. The square measure of each plaque type at the minimum lumen site, which was determined as the point of minimum lumen
size, was also calculated using the VH IVUS software and expressed in square millimeters. The proportion of the area of each plaque type at the minimum lumen site was also determined.

Statistical Analysis

A simple regression analysis was performed to examine the effects of the proportion of the four plaque types at the minimum lumen site on the volumetric proportion of each plaque type. A P value < 0.05 was considered significant. All statistical analyses were performed with the IBM SPSS statistical software package (version 19.0; SPSS Inc, Chicago, IL).

The study was conducted according to the requirements of the institutional review board. The procedures of VH acquisition and periprocedural management were in agreement with the institutional guidelines.

Results

Fifty-six consecutive interventional therapies for cervical carotid artery stenosis in 52 patients were initially included in the present study. One patient with stenosis that was related to radiation therapy and one patient with restenosis after CEA were excluded from the study. Since the VH analyses of the plaque were not available, six stenotic lesions (three stenoses that were too severe for the VH IVUS catheter to cross before predilatation; three stenoses in which the raw RF data captured in the VH IVUS console could not be recorded on a digital video disc because of technical difficulties) were also excluded. The remaining 48 stenotic lesions in 45 patients were analyzed in this study. The descriptive characteristics are shown in Table 1.

The volumetric proportion of each plaque type (fibrous, fibrofatty, dense calcium, and necrotic core), and the proportion of the area of each plaque type at the minimum lumen site are given in Table 2.

The scattergraphs of the volumetric proportion of each plaque type against the proportion of the corresponding plaque type area at the minimum lumen site were drawn (Fig 1). Each regression line, the adjusted coefficient of determination, and its P value were also drawn in the graphs.

Discussion

In the present study, the authors analyzed the relationship between the volumetric composition of the entire carotid plaque and the plaque composition at the minimum lumen site using the simple regression analyses. The adjusted coefficients of determination of the simple regression analyses (Fig 1) were 0.782 for fibrous tissue, 0.741 for fibrofatty tissue, 0.864 for dense calcium, and 0.918 for necrotic core, which indicated a strong correlation. The volumetric proportion of each plaque type correlated significantly with the corresponding plaque type area at the minimum lumen site (Fig 1). This result gives support to the hypothesis that the plaque composition at the minimum lumen site represents the volumetric composition of the entire plaque that causes the stenosis.

The result of the present study is clinically useful for analyzing the relationships between the clinical prognosis of cervical carotid artery stenosis and carotid plaque composition. As described above, periprocedural hypotension in carotid artery stenting can be predicted by volumetric VH IVUS analysis of the plaque responsible for carotid artery stenosis.
volumetric analysis of the plaque is a time-consuming task,\textsuperscript{13,14} analyzing only one cross-section at the minimum lumen site is easier and faster. The result of the present study enables easier prediction of periprocedural hypotension during CAS.

The factor most impeding plaque diagnosis with use of VH IVUS has been that analysis of the volumetric composition of the entire plaque responsible for the carotid artery stenosis is complex and time-consuming. The result of the present study, which enables easy analysis of carotid plaque, may contribute to the development of carotid plaque diagnosis with VH IVUS.\textsuperscript{24,25}

**Limitation of the Present Study**

In the present study, the authors analyzed only atherosclerotic plaque in cervical carotid artery stenosis. Patients with stenosis related to radiation therapy or with restenoses after CEA were excluded from the present study. Further investigation is required for the analysis of these non-atherosclerotic plaques.

**Conclusions**

The result of the present study indicates that the plaque composition at the minimum lumen site represents the volumetric composition of the entire carotid plaque responsible for atherosclerotic cervical carotid artery stenosis.
